## A FASTER SCALING ALGORITHM FOR MINIMIZING SUBMODULAR FUNCTIONS\*

## SATORU IWATA†

Abstract. Combinatorial strongly polynomial algorithms for minimizing submodular functions have been developed by Iwata, Fleischer, and Fujishige (IFF) and by Schrijver. The IFF algorithm employs a scaling scheme for submodular functions, whereas Schrijver's algorithm achieves strongly polynomial bound with the aid of distance labeling. Subsequently, Fleischer and Iwata have described a push/relabel version of Schrijver's algorithm to improve its time complexity. This paper combines the scaling scheme with the push/relabel framework to yield a faster combinatorial algorithm for submodular function minimization. The resulting algorithm improves over the previously best known bound by essentially a linear factor in the size of the underlying ground set.

1. Introduction. Let V be a finite nonempty set of cardinality n. A set function f on V is submodular if it satisfies

$$f(X) + f(Y) \ge f(X \cap Y) + f(X \cup Y) \qquad \forall X, Y \subseteq V.$$

Submodular functions are discrete analogues of convex functions [14]. Examples of submodular functions include cut capacity functions, matroid rank functions, and entropy functions.

The first polynomial-time algorithm for submodular function minimization is due to Grötschel, Lovász, and Schrijver [9]. A strongly polynomial algorithm has also been described by Grötschel, Lovász, and Schrijver [10]. These algorithms rely on the ellipsoid method, which is not efficient in practice.

Recently, combinatorial strongly polynomial algorithms have been developed by Iwata, Fleischer, and Fujishige (IFF) [13] and by Schrijver [16]. Both of these algorithms build on works of Cunningham [2, 3]. The IFF algorithm employs a scaling scheme developed in capacity scaling algorithms for the submodular flow problem [7, 11]. In contrast, Schrijver [16] directly achieves a strongly polynomial bound by introducing a novel subroutine in the framework of lexicographic augmentation. Subsequently, Fleischer and Iwata [5, 6] have described a push/relabel algorithm using Schrijver's subroutine to improve the running time bound. In this paper, we combine the scaling scheme with the push/relabel technique to yield a faster combinatorial algorithm.

Let  $\gamma$  denote the time required for computing the function value of f and M denote the maximum absolute value of f. The IFF scaling algorithm minimizes an integral submodular function in  $O(n^5\gamma \log M)$  time. The strongly polynomial version

runs in  $O(n^7 \gamma \log n)$  time, whereas an improved variant of Schrijver's algorithm runs in  $O(n^7\gamma + n^8)$  time [6].

The time complexity of our new scaling algorithm is  $O((n^4\gamma + n^5) \log M)$ . Since the function evaluation oracle has to identify an arbitrary subset of V as its argument, it is natural to assume  $\gamma$  is at least linear in n. With this assumption, the new algorithm is faster than the IFF algorithm by a factor of n. The strongly polynomial version of the new scaling algorithm runs in  $O((n^6\gamma + n^7)\log n)$  time. This is an improvement over the previous best bound by essentially a linear factor in n.

These combinatorial algorithms perform multiplications and divisions, although the problem of submodular function minimization does not involve those operations. Schrijver [16] asks if one can minimize submodular functions in strongly polynomial time using only additions, subtractions, comparisons, and oracle calls for the function values. Such an algorithm is called "fully combinatorial." A very recent paper [12] settles this problem by developing a fully combinatorial variant of the IFF algorithm. Similarly, we can implement the strongly polynomial version of our scaling algorithm in a fully combinatorial manner. The resulting algorithm runs in  $O(n^8 \gamma \log^2 n)$  time, improving the previous  $O(n^9 \gamma \log^2 n)$  bound by a factor of n.

This paper is organized as follows. Section 2 provides preliminaries on submodular functions. In section 3, we describe the new scaling algorithm. Section 4 is devoted to its complexity analysis. Finally, in section 5, we discuss its extensions as well as a fully combinatorial implementation.

2. Preliminary. This section provides preliminaries on submodular functions. See [8, 14] for more details and general background.

For a vector  $x \in \mathbf{R}^V$  and a subset  $Y \subseteq V$ , we denote  $x(Y) = \sum_{u \in Y} x(u)$ . We also denote  $x^-$  the vector in  $\mathbf{R}^V$  with  $x^-(u) = \min\{x(u), 0\}$ . For each  $u \in V$ , let  $\chi_u$  denote the vector in  $\mathbf{R}^V$  with  $\chi_u(u) = 1$  and  $\chi_u(v) = 0$  for  $v \in V \setminus \{u\}$ . For a submodular function  $f: 2^V \to \mathbf{R}$  with  $f(\emptyset) = 0$ , we consider the base

polyhedron

$$\mathbf{B}(f) = \{x \mid x \in \mathbf{R}^V, \, x(V) = f(V), \, \forall Y \subseteq V : x(Y) \le f(Y)\}.$$

A vector in B(f) is called a base. In particular, an extreme point of B(f) is called an extreme base. An extreme base can be computed by the greedy algorithm of Edmonds [4] and Shapley [17] as follows.

Let  $L = (v_1, \ldots, v_n)$  be a linear ordering of V. For any  $v_i \in V$ , we denote  $L(v_i) = \{v_1, \dots, v_i\}$ . The greedy algorithm with respect to L generates an extreme base  $y \in B(f)$  by

$$(2.1) y(u) := f(L(u)) - f(L(u) \setminus \{u\}).$$

Conversely, any extreme base can be obtained in this way with an appropriate linear ordering.

LEMMA 2.1. Let Q and R be disjoint subsets of V such that  $Q \cup R$  forms an interval in L. Let L' be the linear ordering obtained from L by moving Q to the place immediately after R without changing the orderings in Q and in R. Then the extreme base y' generated by L' satisfies  $y'(q) \le y(q)$  for  $q \in Q$  and  $y'(r) \ge y(r)$  for  $r \in R$ .

*Proof.* For any  $q \in Q$ , we have  $L'(q) \supseteq L(q)$ . Therefore, the submodularity of f implies  $y'(q) = f(L'(q)) - f(L'(q) \setminus \{q\}) \le f(L(q)) - f(L(q) \setminus \{q\}) = y(q)$ . Similarly,  $L'(r) \subseteq L(r)$  holds for  $r \in R$ . Then it follows from the submodularity of f that  $y'(r) = f(L'(r)) - f(L'(r) \setminus \{r\}) \ge f(L(r)) - f(L(r) \setminus \{r\}) = y(r).$ 

For any base  $x \in B(f)$  and any subset  $Y \subseteq V$ , we have  $x^-(V) \le x(Y) \le f(Y)$ . The following theorem shows that these inequalities are in fact tight for appropriately chosen x and Y.

Theorem 2.2. For a submodular function  $f: 2^V \to \mathbf{R}$ , we have

$$\max\{x^-(V)\mid x\in\mathcal{B}(f)\}=\min\{f(Y)\mid Y\subseteq V\}.$$

Moreover, if f is integer-valued, then the maximizer x can be chosen from among integral bases.  $\square$ 

This theorem is immediate from the vector reduction theorem on polymatroids due to Edmonds [4]. It has motivated combinatorial algorithms for minimizing submodular functions.

**3.** A scaling algorithm. This section presents a new scaling algorithm for minimizing an integral submodular function  $f: 2^V \to \mathbf{Z}$ .

The algorithm consists of scaling phases with a scale parameter  $\delta \geq 0$ . It keeps a set of linear orderings  $\{L_i \mid i \in I\}$  of the vertices in V. We denote  $v \leq_i u$  if v precedes u in  $L_i$  or v = u. Each linear ordering  $L_i$  generates an extreme base  $y_i \in B(f)$  by the greedy algorithm. The algorithm also keeps a base  $x \in B(f)$  as a convex combination  $x = \sum_{i \in I} \lambda_i y_i$  of the extreme bases. Initially,  $I = \{0\}$  with an arbitrary linear ordering  $L_0$  and  $\lambda_0 = 1$ .

Furthermore, the algorithm works with a flow in the complete directed graph on the vertex set V. The flow is represented as a skew-symmetric function  $\varphi: V \times V \to \mathbf{R}$ . Each arc capacity is equal to  $\delta$ . Namely,  $\varphi(u,v) + \varphi(v,u) = 0$  and  $-\delta \leq \varphi(u,v) \leq \delta$  hold for any pair of vertices  $u,v \in V$ . The boundary  $\partial \varphi$  is defined by  $\partial \varphi(u) = \sum_{v \in V} \varphi(u,v)$  for  $u \in V$ . Initially,  $\varphi(u,v) = 0$  for any  $u,v \in V$ .

Each scaling phase aims at increasing  $z^-(V)$  for  $z=x+\partial\varphi$ . Given a flow  $\varphi$ , the procedure constructs an auxiliary directed graph  $G_{\varphi}=(V,A_{\varphi})$  with arc set  $A_{\varphi}=\{(u,v)\mid u\neq v,\, \varphi(u,v)\leq 0\}$ . Let  $S=\{v\mid z(v)\leq -\delta\}$  and  $T=\{v\mid z(v)\geq \delta\}$ . A directed path in  $G_{\varphi}$  from S to T is called an augmenting path.

Each scaling phase also keeps a valid labeling d. A labeling  $d: V \to \mathbf{Z}$  is valid if d(u) = 0 for  $u \in S$  and  $v \leq_i u$  implies  $d(v) \leq d(u) + 1$ . A valid labeling d(v) serves as a lower bound on the number of arcs from S to v in the directed graph  $G_I = (V, A_I)$  with the arc set  $A_I = \{(u, v) \mid \exists i \in I, v \leq_i u\}$ .

If there is an augmenting path P, the algorithm augments the flow  $\varphi$  along P by  $\varphi(u,v):=\varphi(u,v)+\delta$  and  $\varphi(v,u):=\varphi(v,u)-\delta$  for each arc (u,v) in P. This procedure is referred to as  $\operatorname{Augment}(\varphi,P)$ . As a result of  $\operatorname{Augment}(\varphi,P)$ , the initial vertex s of P may get rid of S and no new vertex joins S. Thus  $\operatorname{Augment}(\varphi,P)$  does not violate the validity of d.

Let W be the set of vertices reachable from S in  $G_{\varphi}$ , and let Z be the set of vertices that attains the minimum labeling in  $V\backslash W$ . A pair (u,v) of  $u\in W$  and  $v\in Z$  is called *active* for  $i\in I$  if v is the first vertex of Z in  $L_i$  and u is the last vertex in  $L_i$  with  $v\preceq_i u$  and d(v)=d(u)+1. A triple (i,u,v) is also called *active* if (u,v) is active for  $i\in I$ . The procedure Multiple-Exchange(i,u,v) is applicable to an active triple (i,u,v).

For an active triple (i, u, v), the set of vertices from v to u in  $L_i$  is called an active interval. The active interval is divided into Q and R by  $Q = \{w \mid w \in W, v \prec_i w \preceq_i u\}$  and  $R = \{w \mid w \in V \setminus W, v \preceq_i w \prec_i u\}$ .

The procedure Multiple-Exchange(i, u, v) moves the vertices in R to the place immediately after u in  $L_i$ , without changing the ordering in Q and in R. Then it computes an extreme base  $y_i$  generated by the new  $L_i$ . By Lemma 2.1, this results

in  $y_i(q) \ge y_i^{\circ}(q)$  for  $q \in Q$  and  $y_i(r) \le y_i^{\circ}(r)$  for  $r \in R$ , where  $y_i^{\circ}$  denotes the previous  $y_i$ .

Consider a complete bipartite graph with the vertex sets Q and R. The algorithm finds a flow  $\xi: Q \times R \to \mathbf{R}_+$  such that  $\sum_{r \in R} \xi(q,r) = y_i(q) - y_i^{\circ}(q)$  for each  $q \in Q$  and  $\sum_{q \in Q} \xi(q,r) = y_i^{\circ}(r) - y_i(r)$  for each  $r \in R$ . Such a flow can be obtained easily by the so-called northwest corner rule. Then the procedure computes  $\alpha = \min\{\lambda_i, \delta/\beta\}$  with  $\beta = \max\{\xi(q,r) \mid q \in Q, r \in R\}$  and moves x by  $x := x + \alpha(y_i - y_i^{\circ})$ . In order to keep z invariant, the procedure adjusts the flow  $\varphi$  by  $\varphi(q,r) := \varphi(q,r) - \alpha \xi(q,r)$  and  $\varphi(r,q) := \varphi(r,q) + \alpha \xi(q,r)$  for every  $(q,r) \in Q \times R$ . The resulting  $\varphi$  satisfies the capacity constraints due to the choice of  $\alpha$ , and the vertices in W remain reachable from S in  $G_{\varphi}$ .

If  $\alpha = \lambda_i$ , Multiple-Exchange(i, u, v) is called *saturating*. Otherwise, it is called *nonsaturating*. In a nonsaturating Multiple-Exchange(i, u, v), a new index k is added to I. The associated linear ordering  $L_k$  is the previous  $L_i$ . The coefficient  $\lambda_k$  is determined by  $\lambda_k := \lambda_i - \alpha$ , and then  $\lambda_i$  is replaced by  $\lambda_i := \alpha$ . Thus the algorithm continues to keep x as a convex combination  $x = \sum_{i \in I} \lambda_i y_i$ .

Suppose the labeling d is valid before the algorithm applies Multiple-Exchange to an active triple (i,u,v). For any vertex w in the active interval,  $d(v) \leq d(w) + 1$  and  $d(w) \leq d(u) + 1$  hold. These inequalities and d(v) = d(u) + 1 imply  $d(v) \leq d(w) \leq d(u)$ . Note that  $d(v) \leq d(r)$  holds for any  $r \in R \subseteq V \setminus W$ . Hence we have d(r) = d(v) for any  $r \in R$ . If Multiple-Exchange(i,u,v) adds a new arc (s,t) to  $A_I$ , then  $s \in Q$  and  $t \in R$ . Therefore, we have  $d(t) = d(v) \leq d(s) + 1$ . Thus Multiple-Exchange(i,u,v) does not violate the validity of d.

Let h denote the number of vertices in the active interval. The number of function evaluations required for computing the new extreme base  $y_i$  by the greedy algorithm is at most h. The northwest corner rule can be implemented to run in O(h) time, and the number of arcs (q, r) with  $\xi(q, r) > 0$  is at most h - 1. Thus the total time complexity of Multiple-Exchange(i, u, v) is  $O(h\gamma)$ .

If there is no active triple, the algorithm applies Relabel to each  $v \in Z$ . The procedure Relabel(v) increments d(v) by one. Then the labeling d remains valid.

The number of extreme bases in the expression of x increases by one as a result of nonsaturating Multiple-Exchange. In order to reduce the complexity, the algorithm occasionally applies a procedure  $\mathsf{Reduce}(x,I)$  that computes an expression of x as a convex combination of affinely independent extreme bases chosen from the currently used ones. This computation takes  $\mathsf{O}(n^2|I|)$  time with the aid of Gaussian elimination.

We are now ready to describe the new scaling algorithm.

- **Step 0:** Let  $L_0$  be an arbitrary linear ordering. Compute an extreme base  $y_0$  by the greedy algorithm with respect to  $L_0$ . Put  $x := y_0$ ,  $\lambda_0 := 1$ ,  $I := \{0\}$ , and  $\delta := |x^-(V)|/n^2$ .
- **Step 1:** Put d(v) := 0 for  $v \in V$ , and  $\varphi(u, v) := 0$  for  $u, v \in V$ .
- Step 2: Put  $S := \{v \mid z(v) \leq -\delta\}$  and  $T := \{v \mid z(v) \geq \delta\}$ , where  $z = x + \partial \varphi$ . Let W be the set of vertices reachable from S in  $G_{\varphi}$ .
- **Step 3:** If there is an augmenting path P, then do the following.
  - (3-1) Apply Augment( $\varphi, P$ ).
  - (3-2) Apply Reduce(x, I).
  - (3-3) Go to Step 2.
- **Step 4:** Compute  $\ell := \min\{d(v) \mid v \in V \setminus W\}$  and put  $Z := \{v \mid v \in V \setminus W, d(v) = \ell\}$ . If  $\ell < n$ , then do the following.
  - (4-1) If there is an active triple (i, u, v), then apply Multiple-Exchange (i, u, v).
  - **(4-2)** Otherwise, apply Relabel(v) for each  $v \in Z$ .

(4-3) Go to Step 2.

**Step 5:** Determine the set X of vertices reachable from S in  $G_I$ . If  $\delta \geq 1/n^2$ , then apply  $\mathsf{Reduce}(x, I)$ ,  $\delta := \delta/2$ , and go to Step 1.

We now show that the last set X obtained by the scaling algorithm is a minimizer of f.

LEMMA 3.1. At the end of each scaling phase,  $z^-(V) \ge f(X) - n(n+1)\delta/2$ .

Proof. At the end of each scaling phase, d(v) = n for every  $v \in V \setminus W$ . Since d(v) is a lower bound on the number of arcs from S to v in  $G_I$ , this means there is no directed path from S to  $V \setminus W$  in  $G_I$ . Thus we have  $X \subseteq W \subseteq V \setminus T$ , which implies  $z(v) \leq \delta$  for  $v \in X$ . It follows from  $S \subseteq X$  that  $z(v) \geq -\delta$  for  $v \in V \setminus X$ . Since there is no arc in  $G_I$  emanating from X, we have  $y_i(X) = f(X)$  for each  $i \in I$ , and hence  $x(X) = \sum_{i \in I} \lambda_i y_i(X) = f(X)$ . We also have  $\partial \varphi(X) \geq -\delta |X| \cdot |V \setminus X| \geq -n(n-1)\delta/2$ . Therefore, we have  $z^-(V) = z^-(X) + z^-(V \setminus X) \geq z(X) - \delta |X| - \delta |V \setminus X| = x(X) + \partial \varphi(X) - n\delta \geq f(X) - n(n+1)\delta/2$ .  $\square$ 

LEMMA 3.2. At the end of each scaling phase,  $x^-(V) \ge f(X) - n^2 \delta$ .

Proof. The set  $Y = \{v \mid x(v) < 0\}$  satisfies  $x^-(V) = x(Y) = z(Y) - \partial \varphi(Y) \ge z^-(V) - \partial \varphi(Y)$ . Note that  $\partial \varphi(Y) \le \delta |Y| \cdot |V \setminus Y| \le n(n-1)\delta/2$ . Therefore, we have  $x^-(V) \ge z^-(V) - n(n-1)\delta/2$ , which together with Lemma 3.1 implies  $x^-(V) \ge f(X) - n^2 \delta$ .  $\square$ 

Theorem 3.3. At the end of the last scaling phase, X is a minimizer of f.

*Proof.* Since  $\delta < 1/n^2$  in the last scaling phase, Lemma 3.2 implies  $x^-(V) > f(X) - 1$ . Then it follows from the integrality of f that  $f(X) \leq f(Y)$  holds for any  $Y \subseteq V$ .  $\square$ 

**4. Complexity.** This section is devoted to complexity analysis of the new scaling algorithm.

LEMMA 4.1. Each scaling phase performs Augment  $O(n^2)$  times.

Proof. At the beginning of each scaling phase, the set X obtained in the previous scaling phase satisfies  $z^-(V) \geq f(X) - 2n^2\delta$  by Lemma 3.2. For the first scaling phase, we have the same inequality by taking  $X = \emptyset$ . Note that  $z^-(V) \leq z(X) \leq f(X) + n(n-1)\delta/2$  throughout the algorithm. Thus each scaling phase increases  $z^-(V)$  by at most  $3n^2\delta$ . Since each augmentation increases  $z^-(V)$  by  $\delta$ , each scaling phase performs at most  $3n^2$  augmentations.  $\square$ 

LEMMA 4.2. Each scaling phase performs Relabel  $O(n^2)$  times.

*Proof.* Each application of  $\mathsf{Relabel}(v)$  increases d(v) by one. Since  $\mathsf{Relabel}(v)$  is applied only if d(v) < n,  $\mathsf{Relabel}(v)$  is applied at most n times for each  $v \in V$  in a scaling phase. Thus the total number of relabels in a scaling phase is at most  $n^2$ .

Lemma 4.3. The number of indices in I is at most 2n.

*Proof.* A new index is added as a result of nonsaturating Multiple-Exchange. In a nonsaturating Multiple-Exchange (i,u,v), the arc (q,r) that determines  $\beta$  satisfies  $\varphi(q,r) \leq 0$  after the update of  $\varphi$ , and the vertex r in R becomes reachable from S in  $G_{\varphi}$ . This means the set W is enlarged. Thus there are at most n applications of nonsaturating Multiple-Exchange between augmentations. Hence the number of indices added between augmentations is at most n. After each augmentation, the number of indices is reduced to at most n. Therefore,  $|I| \leq 2n$  holds throughout the algorithm.  $\square$ 

In order to analyze the number of function evaluations in each scaling phase, we now introduce the notion of reordering phase. A reordering phase consists of consecutive applications of Multiple-Exchange between those of Relabel or Reduce. By Lemmas 4.1 and 4.2, each scaling phase performs  $O(n^2)$  reordering phases.

LEMMA 4.4. There are  $O(n^2)$  function evaluations in each reordering phase.

*Proof.* The number of function evaluations in Multiple-Exchange(i,u,v) is at most the number of vertices in the active interval for (i,u,v). In order to bound the total number of function evaluations in a reordering phase, suppose the procedure Multiple-Exchange(i,u,v) marks each pair (i,w) for w in the active interval. We now intend to claim that any pair (i,w) of  $i\in I$  and  $w\in V$  is marked at most once in a reordering phase.

In a reordering phase, the algorithm does not change the labeling d nor does it delete a vertex from W. Hence the minimum value of d in  $V\backslash W$  is nondecreasing. After execution of Multiple-Exchange(i,u,v), there will not be an active pair for i until the minimum value of d in  $V\backslash W$  becomes larger. Let Multiple-Exchange(i,s,t) be the next application of Multiple-Exchange to the same index  $i\in I$ . Then we have d(t)>d(v)=d(u)+1, which implies  $v\prec_i u\prec_i t\prec_i s$  in the linear ordering  $L_i$  before Multiple-Exchange(i,u,v). Thus a pair (i,w) marked in Multiple-Exchange(i,u,v) will not be marked again in the reordering phase.

Since  $|I| \leq 2n$  by Lemma 4.3, there are at most  $2n^2$  possible marks without duplications. Therefore, the total number of function evaluations in a reordering phase is  $O(n^2)$ .  $\square$ 

In order to find an active triple efficiently in Step (4-1), we keep track of possible candidates of active triples. For each  $i \in I$  and  $\ell = 1, \ldots, n-1$ , let  $u_{i\ell}$  denote the last vertex u in  $L_i$  such that  $u \in W$  and  $d(u) = \ell - 1$ . Similarly,  $v_{i\ell}$  denotes the first vertex v in  $L_i$  such that  $v \in V \setminus W$  and  $d(v) = \ell$ . Then  $(i, u_{i\ell}, v_{i\ell})$  is an active triple if  $\ell = \min\{d(v) \mid v \in V \setminus W\}$  and  $v_{i\ell} \prec u_{i\ell}$ . At the beginning of each reordering phase, we scan the linear orderings to find all those candidates in  $O(n^2)$  time.

In the rest of the reordering phase, we update the candidates whenever a new vertex is added to W. Let w be the vertex that is added to W. For each  $i \in I$ , if  $u_{i\ell} \leq w$  with  $d(w) = \ell - 1$ , then we replace  $u_{i\ell}$  by w. If  $w = v_{i\ell}$ , then we find the new  $v_{i\ell}$  by scanning  $L_i$ . Thus it takes  $O(n^2)$  time to update the candidates when a new vertex is added to W. Since at most n vertices are added to W, each reordering phase requires  $O(n^3)$  fundamental operations.

THEOREM 4.5. The algorithm performs  $O(n^4 \log M)$  function evaluations and  $O(n^5 \log M)$  arithmetic computations.

*Proof.* Consider the set  $U = \{u \mid x(u) > 0\}$  for the initial base  $x \in B(f)$ . Then we have  $x^-(V) = x(V) - x(U) \ge f(V) - f(U) \ge -2M$ . Therefore, the initial value of  $\delta$  satisfies  $\delta \le 2M/n^2$ . Each scaling phase cuts the value of  $\delta$  in half, and the algorithm terminates when  $\delta < 1/n^2$ . Thus the algorithm consists of  $O(\log M)$  scaling phases.

Since each scaling phase performs  $O(n^2)$  reordering phases, Lemma 4.4 implies that the number of function evaluations in a scaling phase is  $O(n^4)$ . In addition, each reordering phase requires  $O(n^3)$  steps to keep track of active triples. By Lemma 4.1, each scaling phase performs  $O(n^2)$  calls of Reduce, which requires  $O(n^3)$  arithmetic computations. Thus each scaling phase consists of  $O(n^4)$  function evaluations and  $O(n^5)$  arithmetic computations. Therefore, the total running time bound is  $O((n^4\gamma + n^5)\log M)$ .

**5. Discussions.** A family  $\mathcal{D} \subseteq 2^V$  is called a distributive lattice (or a ring family) if  $X \cap Y \in \mathcal{D}$  and  $X \cup Y \in \mathcal{D}$  for any pair of  $X,Y \in \mathcal{D}$ . A compact representation of  $\mathcal{D}$  is given by a directed graph as follows. Let D = (V,F) be a directed graph with the arc set F. A subset  $Y \subseteq V$  is called an ideal of D if no arc enters Y in D. Then the set of ideals of D forms a distributive lattice. Conversely, any distributive lattice  $\mathcal{D} \subseteq 2^V$  with  $\emptyset, V \in \mathcal{D}$  can be represented in this way due to

Birkhoff's representation theorem [1, Theorem 2.5]. Moreover, contracting strongly connected components of D to single vertices, we may assume that the directed graph D is acyclic.

For minimizing a submodular function f on  $\mathcal{D}$ , we apply the scaling algorithm with a minor modification. The modified version uses the directed graph  $G_{\varphi} = (V, A_{\varphi} \cup F)$  instead of  $G_{\varphi} = (V, A_{\varphi})$ . The initial linear ordering  $L_0$  must be consistent with D; i.e.,  $v \leq_i u$  if  $(u, v) \in F$ . Then all the linear orderings that appear in the algorithm will be consistent with D. This ensures that the set X obtained at the end of each scaling phase belongs to  $\mathcal{D}$ . Thus the modification of our scaling algorithm finds a minimizer of f in  $\mathcal{D}$ .

Iwata, Fleischer, and Fujishige [13] also describe a strongly polynomial algorithm that repeatedly applies their scaling algorithm with  $O(\log n)$  scaling phases. The number of iterations is  $O(n^2)$ . Replacing the scaling algorithm by the new one, we obtain an improved strongly polynomial algorithm that runs in  $O((n^6\gamma + n^7)\log n)$  time.

A very recent paper [12] has shown that the strongly polynomial IFF algorithm can be implemented by using only additions, subtractions, comparisons, and oracle calls for function values. Similarly, the new strongly polynomial scaling algorithm can be made fully combinatorial as follows.

The first step towards a fully combinatorial implementation is to neglect Reduce. This causes growth of the number of extreme bases for convex combination. However, the number is still bounded by a polynomial in n. Since the number of indices added between augmentations is at most n, each scaling phase yields  $O(n^3)$  new extreme bases. Hence the number of extreme bases through the  $O(\log n)$  scaling phases is  $O(n^3 \log n)$ .

The next step is to choose an appropriate step length in Multiple-Exchange so that the coefficients should be rational numbers with a common denominator bounded by a polynomial in n. Let  $\theta$  denote the value of  $\delta$  in the first scaling phase. Then  $\kappa = \theta/\delta$  is an integer. For each  $i \in I$ , we keep  $\lambda_i = \mu_i/\kappa$  with an integer  $\mu_i$ . We then modify the definition of saturating Multiple-Exchange. Multiple-Exchange(i,u,v) is now called saturating if  $\lambda_i \xi(q,r) \leq \varphi(q,r)$  for every  $(q,r) \in Q \times R$ . Otherwise, it is called nonsaturating. In nonsaturating Multiple-Exchange(i,u,v), let  $\nu$  be the minimum integer such that  $\nu \xi(q,r) > \varphi(q,r)\kappa$  for some  $(q,r) \in Q \times R$ . Such an integer  $\nu$  can be computed by binary search. Then the new coefficients  $\lambda_k$  and  $\lambda_i$  are determined by  $\mu_k := \mu_i - \nu$  and  $\mu_i := \nu$ . Thus the coefficients are rational numbers whose common denominator is  $\kappa$ , which is bounded by a polynomial in n through the  $O(\log n)$  scaling phases. Then it is easy to implement this algorithm using only additions, subtractions, comparisons, and oracle calls for the function values.

Finally, we discuss time complexity of the resulting fully combinatorial algorithm. The algorithm performs  $O(n^2)$  iterations of  $O(\log n)$  scaling phases. Since it keeps  $O(n^3 \log n)$  extreme bases, each scaling phase requires  $O(n^6 \log n)$  oracle calls for function evaluations and  $O(n^7 \log n)$  fundamental operations. Therefore, the total running time is  $O((n^8 \gamma + n^9) \log^2 n)$ . This improves the previous  $O(n^9 \gamma \log^2 n)$  bound in [12] by essentially a linear factor in n.

In order to reduce this time complexity, McCormick [15] suggests a more efficient implementation for finding active triples. For each  $i \in I$  and  $\ell = 1, ..., n$ , let  $\sigma_{i\ell}$  denote the last vertex s in  $L_i$  with  $d(s) = \ell - 1$ . Similarly,  $\tau_{i\ell}$  denotes the first vertex t in  $L_i$  with  $d(t) = \ell$ . Then there is an active triple (i, u, v) with  $d(v) = \ell$  only if  $\tau_{i\ell} \prec_i \sigma_{i\ell}$ . At the beginning of each reordering phase we scan the linear orderings to

find all  $\sigma_{i\ell}$  and  $\tau_{i\ell}$  in O(n|I|) time. Note that within the reordering phase,  $\sigma_{i\ell}$  and  $\tau_{i\ell}$  are invariant until the algorithm performs Multiple-Exchange(i, u, v) with  $d(v) = \ell$ . Once such a Multiple-Exchange is applied, there will be no active triples for the same i and  $\ell$  in the rest of the reordering phase.

For a pair of i and  $\ell$  with  $\tau_{i\ell} \prec \sigma_{i\ell}$ , we may restrict the search for active triples to the interval between  $\tau_{i\ell}$  and  $\sigma_{i\ell}$  in  $L_i$ . Since these intervals are disjoint, the total number of fundamental operations required for finding active triples is O(n|I|) in each reordering phase. This reduces the number of fundamental operations in a scaling phase to  $O(n^6 \log n)$ . Thus the resulting fully combinatorial algorithm runs in  $O(n^8 \gamma \log^2 n)$  time.

Acknowledgments. The author is grateful to Lisa Fleischer, Satoru Fujishige, Yasuko Matsui, Tom McCormick, and Kazuo Murota for stimulating conversations and helpful comments on the manuscript. The idea of Multiple-Exchange was originally suggested by Satoru Fujishige as heuristics to improve the practical performance of the IFF algorithm. Lisa Fleischer kindly pointed out an error in an earlier version of this paper, and Tom McCormick generously allowed me to include his idea for implementing the algorithm that leads to the bound of the fully combinatorial version. Finally, the author wishes to thank two anonymous referees for many helpful suggestions to improve the presentation of this paper.
